

IMAGE PROCESSING OF PIXELISED IMAGES

[0001] This non-provisional application claims priority under 35 U.S.C. § 119 on Patent Application No. 02079957.3 filed in Europe on November 27, 2002, which is herein incorporated by reference.

BACKGROUND OF THE INVENTION

Field of the Invention

[0002] The present invention is related to the image processing of pixelised images, more particularly to the judgement whether a pixelised image is a monochrome or a colour image. The image processing system may be a stand-alone system or may be part of a scanning and/or image recording and/or printing and/or copying system.

Discussion of the Related Art

[0003] A pixelised image is a digital image or document composed of pixels (picture elements). There are numerous ways to generate a pixelised image such as for instance, by scanning an original image or document using a scanner, or by generating still images using a digital camera or a video camera. Besides the pixelised images generated by a scanner or a digital camera, which are usually in a bitmap format or a compressed bitmap format, also artificially created, e.g. by a computer program, digital images or documents may be offered to the image processing system. The latter images are usually in a structured format including but not limited to a page description language (PDL) format and an extensible markup language (XML) format. Examples of a PDL format are PDF (Adobe), PostScript (Adobe), and PCL (Hewlett-Packard). These structured images can easily be converted by a raster image processor into pixelised images.

[0004] The pixelised images may comprise colour data including colour image data, colour errors, e.g. introduced by scanning a black and white original with a colour scanner, or colour background data, e.g. when scanning an original image printed on a coloured background with a colour scanner.

[0005] For each pixelised image, or parts thereof, the image processing system has to judge whether it is a monochrome image or a colour image. The reliability and quality of this judgement is important for many reasons related to the subsequent processing of the image. One of these reasons is for instance image processing time and memory allocation, particularly when storing the pixelised image. When a monochrome image is misjudged as a colour image, the processing time and storage capacity required is considerably larger compared to storing the image when being judged as a monochrome image. Another reason can be image quality when reproducing the image. For example when a monochrome original is scanned by a colour scanner, recognition of the pixelised image as a colour image and subsequent reproduction thereof by a colour image forming system could result in a severe image quality degradation due to e.g. registering errors. Systems used to reproduce pixelised images include display systems, scanning systems and printing and/or copying systems. A further reason can be throughput and cost as image reproduction on a monochrome image reproduction system is usually cheaper and faster compared to reproduction on a colour reproduction system. Particularly in a professional environment such as e.g. the repro department of a company or a print and/or copy shop, where multiple image reproduction systems are available, including a colour image reproduction system and a black and white image reproduction system and/or a colour image reproduction system capable of operating in a "black only" mode, it is desirable to make optimal use of the resources in order to optimize throughput and costs. Also for the reproduction of a mixed colour image, being an image or a document comprising both coloured and non-coloured parts, it may be beneficial to split the mixed colour image into a colour part and a monochrome part.

[0006] Image processing systems are known, as for instance disclosed in European Patent Application Publication No. EP363146. Such systems are able to split mixed colour images on page level into a colour part and a monochrome part. The colour part contains all the pages of the mixed colour image with colour information. The monochrome part contains all the pages of the mixed colour image with black and white information only. Subsequently, the respective parts are processed by a colour image reproduction system and a black and white

image reproduction system respectively. The sole criterion to judge whether a page is to be classified as a colour page or not is the bare presence of some colour information.

[0007] More advanced algorithms could be used to provide the operator and/or user with the possibility to define a threshold in the colour content, i.e. the amount of colour information present on an image page, or image part or image. If the amount of colour is below the colour threshold, the image is subsequently treated as a monochrome image, even although it may contain a limited amount of colour information, e.g. a coloured line or bullet.

[0008] An image processing system disclosed in European Patent Application Publication No. EP 0 448 330 firstly converts the image data of the pixelised image to a CIE colour space. EP 0 448 330 contains embodiments wherein the saturation value of each individual pixel is compared to a first threshold in order to judge whether it is a colour pixel or not. The colour pixels are counted and compared with a second threshold in order to judge whether the image is a colour image or not. Although this solution may definitely have some merit, a disadvantage thereof is that the colour judgement is performed on individual pixels and is inherently sensitive to colour errors, e.g. pixels having a saturation value different from the original due to a scan read and/or calibration error. EP 0 448 330 further discloses to perform the colour judgement in accordance with a frequency distribution of saturation information of each pixel. In particular, pixels having a saturation value with a high occurrence in the image are decisive in the colour judgement. But a disadvantage of this disclosed method is its lack of sensitivity when judging images having a limited amount of colour, in other words images comprising only colour pixels having a saturation value with a low occurrence in the image.

SUMMARY OF THE INVENTION

[0009] It is an object of the invention to provide an image processing system and method capable of judging whether a pixelised image or a part thereof is a monochrome or a colour image. To increase the reliability of the judgement, instead of making the judgement on the level of an individual pixel, the judgement

should be performed for substantially all the pixels of the image or image part at the same time.

[0010] It is another object of the invention to provide an image processing system and method capable of performing the monochrome/colour judgement for a pixelised image with a high sensitivity, such that colour pixels having a saturation value with a low occurrence are properly taken into account. Preferably the judgement is performed in an automated way.

[0011] It is a further object of the invention to provide an image processing system and method capable of performing the monochrome/colour judgement for a pixelised image independent of the colour space whereto the image data of the pixelised image are referring.

[0012] In an aspect of the invention, there is provided an image processing method for processing a pixelised image, the method comprising the steps of: analyzing pixel data representative of the pixelised image in a colour space and based thereon determining a gray axis, defined as a straight line connecting a white point with a black point; determining for each pixel of the pixelised image the shortest distance to the gray axis; forming a cumulative histogram by plotting for the pixels of the pixelised image a value of the shortest distance versus a cumulative pixel count being the number of associated pixels having at least the value of the shortest distance; and analyzing a relationship between the pixels in the cumulative histogram and based thereon judging whether the pixelised image is to be processed as a monochrome image or a colour image.

[0013] The gray axis is defined as the straight line connecting the white point with the black point. The co-ordinates of the black point and the white point depend on the colour space whereto the pixel data refer. The black point may be the ideal black point and the white point may be the ideal white point. Alternately, the cluster of the darkest pixels, being those pixels of the pixelised image with lack of lightness and lowest chromaticity, may be taken into account to determine the black point, e.g. by defining the black point as the pixel with the average value of luminance of said cluster of darkest pixels, while the lightest pixels may be taken into account to determine the white point. One could also opt to define the black point as that pixel of the pixelised image which is located closest to the ideal black

point, while defining the white point as that pixel of the pixelised image which is located closest to the ideal white point. Other known methods may be equally applied to determine the black point and/or the white point.

[0014] In an embodiment of the invention, when analyzing the relationship between the pixels in the cumulative histogram, only the pixels of the cumulative histogram having an associated cumulative pixel count value equal to or greater than a predetermined threshold are taken into account. Doing so allows the system to decide whether to take small colour objects into account or not in the monochrome/colour judgement by selecting an appropriate threshold.

[0015] In another embodiment of the invention, the relationship between the pixels in the cumulative histogram is determined in an automated way by applying a linear regression analysis to the pixels in said cumulative histogram. When analyzing whether the pixelised image is to be processed as a monochrome image or a colour image, the judgement is based on comparing the value of at least one regression parameter with a predetermined threshold value of said at least one regression parameter. The regression parameters are selected from a group of parameters comprising the correlation coefficient (R), the coefficient of determination (R^2), the slope of the regression line and the intercept of the regression line.

[0016] In another aspect of the invention, there is provided an image processing system for processing a pixelised image, the system comprising: a pre-processor for analyzing pixel data representative of the pixelised image in a colour space and based thereon determining a gray axis, defined as a straight line connecting a white point with a black point, and determining for each pixel of the pixelised image the shortest distance to the gray axis; an analyzer for analyzing a relationship between the pixels of the pixelised image in a cumulative histogram, the cumulative histogram being formed by plotting for the pixels of the pixelised image a value of the shortest distance versus a cumulative pixel count being the number of associated pixels having at least the value of the shortest distance; and a judging unit for judging, based on the relationship between the pixels in the cumulative histogram, whether the pixelised image is to be processed as a monochrome image or a colour image.

[0017] These and other objects of the present application will become more readily apparent from the detailed description given hereinafter. However, it should be understood that the detailed description and specific examples, while indicating preferred embodiments of the invention, are given by way of illustration only, since various changes and modifications within the spirit and scope of the invention will become apparent to those skilled in the art from this detailed description.

BRIEF DESCRIPTION OF THE DRAWINGS

[0018] The present invention will become more fully understood from the detailed description given hereinbelow and the accompanying drawings which are given by way of illustration only, and thus are not limitative of the present invention and wherein:

[0019] Figure 1 depicts a schematic representation of an image processing system for processing pixelised images according to an embodiment of the invention.

[0020] Figure 2 depicts a flowchart for operating an image processing system as e.g. depicted in Fig. 1 so as to judge whether a pixelised image is to be further processed as a monochrome or a colour image according to an embodiment of the invention.

[0021] Figure 3a is an example of a monochrome photograph.

[0022] Figure 3b is a representation of the pixelised photograph of Fig. 3a in the CIE $L^*a^*b^*$ colour space.

[0023] Figure 3c is a cumulative histogram of the pixelised photograph of Fig. 3a according to an embodiment of the invention.

[0024] Figure 4a is an example of a monochrome representation of a black and white text document on a yellowed paper background.

[0025] Figure 4b is a representation of the pixelised text document of Fig. 4a in the CIE $L^*a^*b^*$ colour space.

[0026] Figure 4c is a reproduction of the black and white text document of Fig. 4a after background correction by translating and rotating the gray axis of the pixelised image.

[0027] Figure 5a is an example of a monochrome representation of a monochrome document including some small colour objects.

[0028] Figure 5b is a representation of the pixelised document of Fig. 5a in the CIE L*a*b* colour space.

[0029] Figure 5c is a cumulative histogram of the pixelised document of Fig. 5a according to an embodiment of the invention.

[0030] Figure 6a is an example of a monochrome representation of a full colour picture.

[0031] Figure 6b is a representation of the pixelised picture of Fig. 6a in the CIE L*a*b* colour space.

[0032] Figure 6c is a cumulative histogram of the pixelised picture of Fig. 6a according to an embodiment of the invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0033] In relation to the appended drawings, the present invention is described in detail in the sequel. Several embodiments are disclosed. It is apparent however that a person skilled in the art can imagine other equivalent embodiments or other ways of executing the present invention, the scope of the present invention being limited only by the terms of the appended claims.

[0034] According to a preferred embodiment of the present invention, the image processing system (1), as schematically depicted in Figure 1, comprises a pre-processor (4), an analyzer (3), a judging unit (2) and optionally a converter (5). The image processing system (1) may be incorporated in a computer, which may be coupled by a network or any other interface to one or more image reproduction systems. The image processing system (1) may also be part of an image reproduction system. Examples of image reproduction systems are display systems, scanning systems, image recording systems and printing and/or copying systems. All the components of the image processing system (1) are operatively coupled.

[0035] Any pixelised image (6) may be offered to the pre-processor (4) of the image processing system. However, as indicated in Fig. 1, the pixelised image (6) may be generated by scanning an original image or document (9) using a colour scanner (10). The size of the pixels depends on the optical resolution of the illumination device. The generated pixelised images are composed of a number of colour separation images dependent on the colour space used, in case of scanned images typically the sRGB colour space is used. Therefore, these generated pixelised images are composed of three separation images respectively of the process colours red (R), green (G) and blue (B). The image signals associated with the separation images typically specify for each pixel an image density value using a 24-bit representation, i.e. 8-bits per process colour. A 8-bit representation enables to define 256 levels per process colour each corresponding with a particular tonal value. Optionally the converter (5) may convert the image signals of the sRGB colour space associated with the pixelised image to image signals of a different colour space. Of particular interest are the device independent colour spaces of the CIE ("Commission Internationale d'Eclairage"), such as e.g. the XYZ colour space, the xyY colour space, the $L^*a^*b^*$ colour space and the $L^*u^*v^*$ colour space.

[0036] Thereafter the pre-processor (4) enables to pre-process the image signals, e.g. to correct colour errors, and determines the gray axis. The analyzer (3) calculates for each pixel of the pixelised image the shortest distance to the gray axis and keeps track of the cumulative pixel count being the number of pixels associated with a particular distance to the gray axis, namely all the pixels having a shortest distance value to the gray axis of at least said particular distance. For all pixels, the logarithm of the cumulative pixel count versus the distance to the gray axis is plotted on a display (12) for further analysis. When the pixelised image represents a monochrome image, a linear relationship between the logarithm of the cumulative pixel count and the distance to the gray axis is expected irrespective of the colour space used. The analysis of the plot can be facilitated by employing a fitting routine (11). The fitting routine (11) analyzes the pixels using a linear regression analysis. The obtained regression line can be displayed together with the pixel data using the display (12).

[0037] Based on the analysis data and optionally on the values of the regression parameters, the judging unit (2) decides whether the pixelised image (or part thereof) is a monochrome image or a colour image. The judging unit (2) may mark the pixelised image accordingly for further processing in either a monochrome processing channel (7) or a colour processing channel (8). Optionally, a converter may be provided (not shown) to convert the image signals associated with the pixelised image. For instance, in case the pixelised image is judged to be in colour, the associated image signals may be converted to another colour space, e.g. a colour space associated with the process colours of the colour processing channel, while in case the pixelised image is judged to be in monochrome, the associated image signals may be converted into a monochrome image signal.

[0038] An example of a colour processing channel is a colour image reproduction system. An example of a monochrome processing channel is a monochrome image reproduction system, including a colour image reproduction system capable of operating in a monochrome mode. The dual processing channel configuration according to the present invention may also be applied for the archiving of the pixelised images where in the respective processing channels different compression techniques are employed to process and store pixelised images or parts thereof.

[0039] Optionally, when the pixelised image is a mixed colour/ monochrome image, one may opt to split the image using a splitter (13) into a monochrome part and a colour part. The monochrome part comprises all the image parts being judged as monochrome and/or marked to be further processed in a monochrome processing channel. The colour part comprises all the image parts being judged as colour and/or marked to be further processed in a colour processing channel.

[0040] When operating an image processing system such as the system of Fig. 1 according to the present invention, a process flow as schematically depicted in Fig. 2 may be executed. Referring to Fig. 2, at start (20), at least the first image part (21) of a pixelised image is retrieved by the pre-processor (4) of the image processing system. The pre-processor (4) determines the colour space associated with the part of the pixelised image. Optionally, the image signals associated with

the pixelised image may be converted to another colour space, preferably a device-independent colour space of the CIE.

[0041] Once the colour space is established, the gray axis is determined. The gray axis is defined as the straight line connecting the white point with the black point. The ideal black point and the ideal white point may be taken. For example in a RGB colour space, using a 24-bit representation, the ideal black point is referred to as (0,0,0), while the ideal white point is (255, 255, 255). In the CIE $L^*a^*b^*$ colour space, the ideal gray axis coincides with the luminance (lightness) axis, i.e. the achromatic colours or in other words $a^*=0$ and $b^*=0$. The ideal black point in $L^*a^*b^*$ is referred to as (0,0,0), while the ideal white point is referred to as (100,0,0) using a lightness scale from 0 to 100. In practice, however, in order to compensate for colour errors and/or background colour, the black point and/or white point may be determined otherwise. For instance, the cluster with the darkest pixels (lack of lightness) and lowest chromaticity of the pixelised image may be taken into account to determine the black point, while the lightest pixels may be taken into account to determine the white point.

[0042] Once the equation of the gray axis is established, the image data of each individual pixel (22) of the pixelised image is retrieved and for each pixel the shortest distance to the gray axis is calculated (23, 19 and 18). If all the pixels have been processed to calculate the shortest distance to the gray axis, then a cumulative histogram (24) is formed wherein, for all pixels, the logarithm of the cumulative pixel count versus the distance to the gray axis is plotted. Plotting the logarithm of the cumulative pixel count attributes significant weight to a small number of pixels at a large distance from the gray axis or in other words pixels with a high chromaticity. This renders the system of the present invention highly sensitive such that small amounts of colour can be recognized. Subsequently the cumulative histogram is analyzed and based thereon a judgement (25) is made whether the processed image part is in monochrome or colour. Thereafter the next image part, if any, may be retrieved and the whole process flow can be repeated until all the image parts are processed (15, 16 and 17).

[0043] The data analysis (25) can be supplemented and the subsequent judgement may be facilitated by fitting the data (26). Preferably the data are fitted

employing a linear regression method. A regression analysis (27) is performed by selecting at least one regression parameter and comparing it with a predetermined value to make the colour (28)/monochrome (29) judgement. Examples of regression parameters which may be useful in the analysis are the correlation coefficient (R), the coefficient of determination (R^2), the slope of the regression line and the intercept of the regression line.

[0044] When performing the colour/monochrome judgement according to the present invention, a colour threshold can be taken into account. For instance, suppose an image comprising a colour object which is 0.01 % or less of the image or image part is not to be considered as a colour image. According to the present invention a cut-off value for the cumulative pixel count can be defined in the cumulative histogram such that 99.99% percent of the pixels are taken into account in the analysis (25) and data fit (26), while the 0.01% of the pixels having the highest chromaticity values are excluded.

[0045] Different examples of judging whether a pixelised image is a monochrome or colour according to the present invention are now provided below.

Example 1

[0046] An original, in casu a monochrome photograph, as depicted in Fig. 3a, is scanned using a colour scanner. As a result a pixelised image is obtained which is used as input for the pre-processor (4) of the image processing system according to the present invention. The pixelised image is composed of colour separation images in the RGB colour space. The image signals associated with the respective separation images are converted to image signals associated with the CIE $L^*a^*b^*$ colour space. An advantage of the CIE $L^*a^*b^*$ colour space is that colour is represented as perceived by the human eye. In Fig. 3b, all pixels of Fig. 3a are represented in the CIE $L^*a^*b^*$ colour space.

[0047] To determine the gray axis, the ideal black point (0,0,0) and the ideal white point (100,0,0) are taken or in other words the gray axis coincides with the luminance axis. Subsequently the analyzer (3) can calculate for each pixel the shortest distance to the gray axis. For all pixels, the logarithm of the cumulative pixel count (31) versus the distance to the gray axis is subsequently plotted in the

cumulative histogram as depicted in Fig. 3c. As can be seen in this cumulative histogram, the relationship depicted by the curve (31) is a linear one, as expected for a monochrome image. Thus, the pixelised image is judged to be a monochrome image. This is confirmed by the linear regression analysis yielding a regression curve (32) with a coefficient of determination (R^2) equal to 0.996 ($R^2=1$ means a perfect straight line). As can be expected, the slope of the regression line is very steep while the value of the intercept is high. These are all indications that the image is a monochrome pixelised image.

[0048] The operator or may perform the colour/monochrome judgement himself and process the pixelised image accordingly. Alternately, threshold values for one or more regression parameters may be used to compare with the obtained regression parameter values such that the monochrome/colour judgement can be made in an automated way by the image processing system.

[0049] Once the judgement is made, one could opt to process the pixelised image such that a single separation image of the black process colour remains, or in other words a conversion to a true monochrome image could be executed. Doing so reduces the size of the pixelised image which is both beneficial with respect to storage capacity as well as processing time in subsequent processing steps. Moreover, the removal of colour errors is likely to enhance image quality.

Example 2

[0050] An original, in casu a black and white text document on a paper background as depicted in Fig. 4a, is scanned using a colour scanner. Originally the paper background was white, but the influence of the sunlight resulted in a yellowed paper background (41). As a result of the colour scan, a pixelised image is obtained which is used as input for the pre-processor (4) of the image processing system according to the present invention. The pixelised image is composed of colour separation images in the RGB colour space. The image signals associated with the respective separation images are converted to image signals associated with the CIE $L^*a^*b^*$ colour space. In Fig. 4b, all pixels of Fig. 4a are represented in the CIE $L^*a^*b^*$ colour space. As can be observed in Fig. 4b, there are two clusters of pixels: a white-yellow cluster (42) composed of the

background pixels, and a black cluster (43) composed of the text characters. The gray axis (44) is determined by the pre-processor (4) as the straight line connecting the black point and the white point and is clearly different from the ideal gray axis. The white point is obtained by averaging the pixels of the white-yellow cluster (42), while the black point is obtained by averaging the pixels of the black cluster (43). Subsequently the analyser (3) can calculate for each pixel the shortest distance to the gray axis (44). For all pixels, the logarithm of the cumulative pixel count versus the distance to the gray axis can subsequently be plotted in a cumulative histogram. Although not shown, the result (generally linear) is comparable with the histogram obtained in Example 1 above as depicted in Fig. 3c. In this Example 2, the judgement is therefore again monochrome.

[0051] Once this judgement is made, one could opt to process the pixelised image such that the gray axis coincides with the ideal gray axis (i.e. the luminance axis) by subjecting the pixels to at least a rotation and translation step. The result hereof is depicted in Fig. 4c. One could even opt to include a monochrome/black-and-white judgement once it is established that the pixelised image is not a colour image. Once it is established that the image is a true black-and-white image, i.e. without gray levels, one could opt to process the pixelised image such that a conversion to a true black-and-white image is executed. Doing so even further reduces the size of the pixelised image as only a single bit per pixel is required instead of 8-bits in case of a monochrome or 24-bits in case of a colour image.

Example 3

[0052] An original, in casu a monochrome document with a very small amount of colour, as depicted in Fig. 5a, is scanned using a colour scanner. The document includes two small colour objects: a green circle (51) to highlight a character, and some brown coffee spots (52) formed by spilling coffee on the document. As a result of the colour scan, a pixelised image is obtained which is used as input for the pre-processor (4) of the image processing system according to the present invention. The pixelised image is composed of colour separation images in the RGB colour space. The image signals associated with the respective separation images are converted to image signals associated with the

CIE L*a*b* colour space. In Fig. 5b all pixels of Fig. 5a are represented in the CIE L*a*b* colour space. As can be observed in Fig. 5b, there are two small clusters of colour pixels: a cluster (54) composed of the pixels of the green colour object (51), and a cluster (55) composed of the pixels of the brown colour object (51). The pre-processor (4) determines the equation of the gray axis (53) which almost coincides with the ideal gray axis.

[0053] Subsequently the analyzer (3) calculates for each pixel the shortest distance to the gray axis. For all pixels, the logarithm of the cumulative pixel count (56) versus the distance to the gray axis is plotted in the cumulative histogram as depicted in Fig. 5c. As can be seen in this cumulative histogram, the brown cluster (55) and the green cluster (54) are not linear and clearly visualized demonstrating the sensitivity of the image processing system according to the present invention to detect small amounts of colour. The image is therefore judged to be in colour. This is confirmed by the linear regression analysis yielding a regression curve (57) with a coefficient of determination (R^2) equal to about 0.7. The slope of the regression line is still steep while the value of the intercept is lowered. Particularly, a threshold value for the coefficient of determination (R^2) may be used to compare with the obtained value such that the monochrome/colour judgement is made in an automated way by the image processing system.

[0054] In this example it is questionable whether one wishes to treat the coloured objects as colour or not in further processing steps. Therefore after the colour recognition, one could further process the data in order to determine whether the colour in the image is functional or not. This can be done by the user/operator or in an automated way using a rule base. Such a system is disclosed in co-pending European Patent Application No. 02077078.0 (filing date of May 27, 2002).

Example 4

[0055] An original, in casu a colour picture, which is depicted in Fig. 6a as a monochrome picture, is scanned using a colour scanner. The document includes all kind of colours distributed over the entire colour space. As a result of the colour scan, a pixelised image is obtained which is used as input for the pre-processor

(4) of the image processing system according to the present invention. The pixelised image is composed of colour separation images in the RGB colour space. The image signals associated with the respective separation images are converted to image signals associated with the CIE L*a*b* colour space. In Fig. 6b, all pixels of Fig. 6a are represented in the CIE L*a*b* colour space. As can be observed in Fig. 6b, there the pre-processor (4) determines the equation of the gray axis which almost coincides with the ideal gray axis.

[0056] Subsequently the analyser (3) calculates for each pixel the shortest distance to the gray axis. For all pixels, the logarithm of the cumulative pixel count (61) versus the distance to the gray axis is plotted in the cumulative histogram as depicted in Fig. 6c. As can be seen in this cumulative histogram, there is no linear relation between the logarithm of the cumulative pixel count and the distance to the gray axis. The image is therefore judged to be a colour image. This is confirmed by the linear regression analysis yielding a regression curve (62) with a coefficient of determination (R^2) equal to about 0.5. The slope of the regression line is low and the value of the intercept is also low. These are all indications that the pixelised image is a colour pixelised image.

[0057] The operator may perform the colour/monochrome judgement himself and process pixelised image accordingly. Alternately, threshold values for one or more regression parameters may be used to compare with the obtained regression parameter values such that the monochrome/colour judgement can be made in an automated way by the image processing system.

[0058] The invention being thus described, it will be obvious that the same may be varied in many ways. Such variations are not to be regarded as a departure from the spirit and scope of the invention, and all such modifications as would be obvious to one skilled in the art are intended to be included within the scope of the following claims.
